PowerPC™

Application Note

A Minimal PowerPC™ Boot Sequence for Executing Compiled C Programs

Becky L. Gill
PowerPC Core Design Technologies/Architecture & Performanc
risc10@email.sps.mot.com

This document describes the procedures necessary to successfully initialize a PowerPC processor and begin executing programs compiled using the PowerPC embedded application interface (EABI). The items discussed in this document have been tested for PowerPC 603e, and PowerPC 750 microprocessors. The methods and source code presented in this document may work unmodified on similar PowerPC platforms as well.

This document contains the following topics:

- Part I, “Overview,” provides an overview of the conditions and exceptions for the procedures described in this document.
- Part II, “PowerPC Processor Initialization,” provides information on the general setup of the processor registers, caches, and MMU.
- Part III, “PowerPC EABI Compliance,” discusses aspects of the EABI that apply directly to preparing to jump into a compiled C program.
- Part IV, “Sample Boot Sequence,” describes the basic operation of the boot sequence and the many options of configuration; explains in detail a sample configurable boot and how the code may be modified for use in different environments; and discusses the compilation procedure using the supporting GNU build environment.
- Part V, “Source Files,” contains the complete source code for the files ppcinit.S, ppcinit.h, ld.script, and Makefile.

Part I Overview

This section provides a brief overview of some of the procedures described in this document.

It is useful to be able to run benchmarks or other computationally intensive user programs on a processor without the overhead or interference of an operating system (OS). Also, there are stages during hardware development where an OS may not be readily available or convenient.

The procedures discussed in this document perform only the minimum amount of work necessary to execute a user program. The sample boot sequence is designed to run from system reset. It does not contain exception handling facilities for other exceptions, although the code is located so that it doesn't interfere with exception space. This allows users who wish to provide exception handling to add exception code without modifying this source. In addition, this code only handles processor setup. It does not initialize any peripheral devices since it is designed to be run on Instruction Set Simulators, test cards, or small evaluation boards. No input/output interface is provided. Results are obtained by looking at data saved in memory via hardware debuggers or simulator commands.

The sample boot sequence uses the PowerPC memory management unit (MMU) to provide basic access protection for the ROM and RAM regions of memory via BAT. The more advanced features of the MMU, which provide support for paging and segmentation, are not utilized.

The sample boot sequence provided should be linked with a user program to create a ROM image. This image is then loaded into a ROM device located at the default system reset vector. The sample boot sequence handles the task of relocating the code and data from ROM to RAM where necessary and then allows the user program to execute. Upon completion, the boot sequence will save timing information for the user code and branch to the invalid opcode exception vector.

Part II PowerPC Processor Initialization

This section describes the state of the PowerPC processor at power-up, the MMU, the caches, and the EABI register initialization.

2.1 General Initialization

At power-up, the PowerPC processor will be in a minimal state, with most features, such as caching and address translation, disabled. External interrupts, the machine check exception, and floating-point exceptions will also be disabled. On most systems, the processor starts up in big-endian mode with the exception prefix set to 0xFFF0_0000. This means that upon System Reset (exception vector 0x0100), the processor will execute code beginning at 0xFFF0_0100. There are some PowerPC configurations where the exception prefix is determined by the state of a pin coming in to the processor. For these systems, care must be taken to locate the boot code so that it is executed upon system reset. For the purposes of this paper, the default exception prefix will be assumed to be 0xFFF0_0000.

The code located at the system reset vector must handle system initialization. Reset vectors on the PowerPC are located at increments of 0x0000_0100 from the vector table start address. Since the initialization code must fit between the allocated hard reset exception space between 0xFFF0_0100 and 0xFFF0_01FF (or 0x0000_0100 and 0x0000_01FF, depending on the location of the vector table), it is customary for the reset code to branch to an address beyond the end of the exception table's allocated space and execute the instruction sequence located there. Addresses starting at 0xFFF0_0100 (or 0x0000_0100) and ending at 0xFFF0_3000 (or 0x0000_3000) are reserved for the vector table. The sample boot code found at the end of this document follows this procedure.

A typical initialization sequence performs any necessary processor setup or hardware-specific initialization, and then enables exceptions. This includes external interrupts, the machine check exception, and floating-point exceptions. In addition, if the vector table is to be relocated once the hardware setup is complete, the exception prefix (IP) bit of the machine state register (MSR) must be changed to reflect the new location of the vector table.

2.2 Memory Management Unit

A boot program will need to set up the MMU, if memory management is required. Using the MMU to translate accesses to memory addresses allows the programmer to specify protections and access controls for individual regions of memory. For a minimal system with four or fewer memory regions, it is sufficient to use block address translation (BAT) to perform a rudimentary mapping. For more complicated systems, the segment registers and page tables need to be initialized. This document only deals with the minimal configuration using the BAT registers.

The MMU information provided in this document is included for convenience and is not complete. For more information about using BAT and the MMU, refer to the *PowerPC Microprocessor Family: The Programming Environments for 32-Bit Microprocessors*.

When using the MMU to provide address translation via the BAT registers, each region of memory in the system should have an associated BAT mapping. These mappings allow the programmer to specify options such as whether the specified address range is valid for supervisor or user mode, the memory/cache access mode, and the protection bits for the block. There are eight BAT array entries. Four of these map data regions (DBATs), while the remaining four entries specify instruction regions (IBATs). Each entry consists of two registers, one used to specify the upper 32 bits of the BAT entry and the other the lower 32 bits. The different fields of these registers are shown in Table 1 and Table 2.

Table 1. Upper BAT Register Format

Bits	Name	Description
0–14	BEPI	Block effective page index—Compared with high-order bits of the logical address to determine if there is a hit in that BAT array entry
15–18	—	Reserved
19–29	BL	Block length—Encoding of the length of the block, ranging from 128 Kbytes to 256 Mbytes. See Table 3 for details.
30	Vs	Supervisor mode valid bit—Along with MSR[PR], specifies whether this block is valid in supervisor mode
31	Vp	User mode valid bit—Along with MSR[PR], specifies whether this block is valid in user mode.

Table 2. Lower BAT Register Format

Bits	Name	Description
0–14	BRPN	Used with the BL field to determine the high-order bits of the physical address of the block.
15–24	—	Reserved

Table 2. Lower BAT Register Format (Continued)

Bits	Name	Description
25-28	WIMG	Memory/cache access mode bits. W = Write-through I = Cache inhibited M = Memory coherence G = Guarded The W and G bits should not be written to in the IBAT registers: doing so produces boundedly undefined results.
29	—	Reserved
30-31	PP	Protection bits for block—Used in combination with Vs and Vp in the upper BAT to determine the protection for the block. See Table 4 for details.

The procedure for initializing a pair of BAT registers is as follows:

1. Disable the MMU.
2. Initialize the lower portion of the BAT array entry.
3. Initialize the upper portion of the BAT array entry.
4. Execute an **isync** instruction.
5. Re-enable the MMU once all setup is complete.

Unused BAT registers should be invalidated by clearing the Vs and Vp bits in the upper BAT register.

For each region of memory to be mapped, an appropriate BL and BEPI must be chosen. The BL field is an encoding of the length of the block to be mapped. The BEPI field corresponds to the upper bits of the logical address of a region to be mapped onto physical memory. During address translation, addresses are compared with the BEPI field to determine if a BAT array hit has occurred.

Next, the BRPN must be chosen to indicate the physical memory onto which the logical region specified by the BEPI is to be mapped. For many minimal systems where the logical and physical addresses are equivalent, including the sample located at the end of this document, the BEPI and BRPN will be equal. Note that the values in the BEPI and BRPN fields must have at least as many low order zeroes as the BL has ones. Otherwise, the results are boundedly undefined. The possible BL encodings are shown in Table 3.

Table 3. BL Encodings

Block Size	BL Encoding
128 Kbytes	000 0000 0000
256 Kbytes	000 0000 0001
512 Kbytes	000 0000 0011
1 Mbyte	000 0000 0111
2 Mbytes	000 0000 1111
4 Mbytes	000 0001 1111
8 Mbytes	000 0011 1111

Table 3. BL Encodings (Continued)

Block Size	BL Encoding
16 Mbytes	000 0111 1111
32 Mbytes	000 1111 1111
64 Mbytes	001 1111 1111
128 Mbytes	011 1111 1111
256 Mbytes	111 1111 1111

The Vs and Vp bits in the upper BAT register, along with the PP bits in the lower BATs, specify the access controls for the memory region. A region may be marked valid for supervisor mode, valid for user mode, or valid for both modes. Table 4 shows these options.

Table 4. Block Access Protection Control

Vs	Vp	PP	Block Type
0	0	xx	No BAT match
0	1	00	User—no access
1	0	00	Supervisor - no access
0	1	x1	User—read only
1	0	x1	Supervisor - read only
0	1	10	User—read/write
1	0	10	Supervisor - read/write
1	1	00	Both - no access
1	1	x1	Both - read only
1	1	10	Both - read/write

In addition, the programmer may specify the memory/cache access modes for the mapped region. These modes are controlled by the WIMG bits in the lower BAT registers.

Setting the W bit for a memory region causes writes to the region to be written through to main memory every time a cached copy of the region is modified. If the W bit is set to 0, accesses are treated as write-back; that is, they are not written into memory until the block is flushed from the cache.

The I bit controls the caching of the region. If the I bit is set to 1, the region becomes cache-inhibited, and all accesses to the region must take place from main memory. This bit should usually be set for regions that encompass I/O device memory. Since these devices may dynamically update a memory location, reading a cached copy can result in accessing old data. Marking the region cache-inhibited prevents this problem.

The M bit specifies memory coherency. When it is set to 0, the hardware does not enforce data coherency. Otherwise, accesses to regions with the M bit set cause the hardware to indicate to the rest of the system that the access occurred. This bit is useful for systems where multiple processors or other DMA devices can modify the memory. In a minimal single-processor system with no DMA devices, the M-bit should be set to 0.

The G bit marks a memory region as guarded when set to 1. The guarded attribute protects an area of memory from read accesses that are not directly specified by the program. It is especially useful for memory regions that have holes. Whenever the processor tries to speculatively load a block of data, it may attempt

to access memory that does not exist. This can cause a machine check exception. Marking the region as guarded prevents this from occurring. In addition, the guarded attribute can be used to prevent speculative load operations to device memory, which can cause unpredictable behavior.

In a complete operating system, MMU setup continues with invalidating TLB entries, initializing the segment registers, and setting up the page table. Even if only BAT mappings are used for translation, it is possible that a user program may generate accesses to addresses that are invalid or not mapped by the BAT registers. In this case, the hardware will attempt to look at the page table to resolve the reference. If the page table pointer and entries have not been initialized, it is possible that they may contain random data and cause unintended memory accesses. This document will not describe how to perform these actions. Refer to the *PowerPC Microprocessor Family: The Programming Environments for 32-Bit Microprocessors* or the specific reference manual for a particular processor for more information.

Once the MMU setup completes, the MMU may be enabled by setting MSR bits 26 and 27, Instruction Address Translation (IR) and Data Address Translation (DR). At this point, address translation is active.

2.3 Caches

At power-up, the instruction and data caches are disabled and invalidated. These can be turned on to boost program performance. For the PowerPC 603, PowerPC 603e, and PowerPC 750, turning on the caches requires setting bit 16, instruction cache enable (ICE), and bit 17, data cache enable (DCE) in hardware implementation register 0 (HID0). An **isync** instruction should be issued before setting the ICE bit to ensure that the cache is not enabled or disabled during an instruction fetch. Similarly, a **sync** instruction should be executed before setting the DCE bit.

Note that simply enabling the caches is not sufficient to ensure that the caches will be used. Memory regions where the user data resides should be mapped as non-cache-inhibited in order to make use of the cache. See Section 2.2, “Memory Management Unit,” for more information on mapping memory regions.

2.4 EABI Register Initialization

Before a boot sequence can jump into the user program, the processor registers expected to contain specific values for the Embedded Application Binary Interface (EABI) must be set up appropriately. The three registers that the boot sequence must initialize are GPR1, GPR2, and GPR13. In addition, some registers may be modified during execution of the compiled program. Part III, “PowerPC EABI Compliance,” describes these registers in more detail.

Part III PowerPC EABI Compliance

The PowerPC EABI specifies the system interface for compiled programs. The EABI is based on the *System V Application Binary Interface* and the *PowerPC Processor Supplement*. For general ABI documentation, refer to these documents, as well as the *PowerPC Embedded Application Binary Interface*. This document only includes aspects of the EABI that apply directly to preparing to jump into a compiled C program.

For running compiled programs, the EABI-specified register conventions must be followed. The EABI defines how the processor’s registers are to be used by a conforming application. Table 5 lists the register conventions for the PowerPC EABI:

Table 5. PowerPC EABI Registers

Register	Contents
GPR1	Stack Frame Pointer
GPR2	_SDA2_BASE

Table 5. PowerPC EABI Registers (Continued)

Register	Contents
GPR13	_SDA_BASE
GPR31	Local variables or environment pointer
GPR0	Volatile—may be modified during linkage
GPR3, GPR4	Volatile—used for parameter passing and return values
GPR5–GPR10	Used for parameter passing
GPR11–GPR12	Volatile—may be modified during linkage
GPR14–GPR30	Used for local variables
FPR0	Volatile register
FPR1	Volatile—used for parameter passing and return values
FPR2–FPR8	Volatile—used for parameter passing
FPR9–FPR13	Volatile registers
FPR14–FPR31	Used for local variables

The symbols _SDA_BASE and _SDA2_BASE will be defined during linking. They specify the locations of the small data areas. The boot sequence must load these values into GPR13 and GPR2, respectively, before branching to the user code entry point.

The small data areas contain part of the data of the executable. They hold a number of variables that can be accessed within a 16-bit signed offset of _SDA_BASE or _SDA2_BASE. References to these variables are performed through references to GPR13 and GPR2 by the user program. Typically, the small data areas contain program variables that are less than or equal to 8 bytes in size, although this differs by compiler. The variables in SDA2 are read-only.

The boot code must also set up the stack pointer in GPR1. This pointer must be 8-byte aligned for the EABI (as opposed to 16-byte aligned for the PowerPC ABI) and should point to the lowest allocated valid stack frame. The stack grows toward lower addresses, so its location should be selected so that it does not grow into data or bss areas.

The remainder of the registers are listed for completeness and are not modified by the minimal boot code. They may be modified by the user program.

Part IV Sample Boot Sequence

The sample boot sequence in this section completes minimal processor setup and executes a user program. It performs only processor setup (no peripheral devices), and leaves external interrupts disabled. It is designed for use with test cards, evaluation boards, or processor simulators where the developer can directly view the contents of memory to verify correct program execution. This code sequence is designed to take the place of the traditional crt0 module, as well as to provide hardware initialization normally performed by the operating system.

The basic operation of the boot sequence is as follows:

1. Invalidate the BAT entries.
2. Set up the BAT registers to provide address translation and protection.
3. Invalidate all TLB entries.
4. Turn on address translation.

5. Relocate the text, data, and bss sections from ROM to RAM.
6. Enable the caches.
7. Set up EABI registers GPR1, GPR2, GPR13.
8. Place user code main entry address in SRR0.
9. Put the MSR value for the user program into SRR1.
10. Save the return address in the link register.
11. Execute **rfi.** This will execute the user program by jumping to the address stored in SRR0.
12. Initialize the time base to 0.
13. Save the time base register values into memory (useful for timing benchmarks).
14. Branch to invalid op vector to indicate completion.

This procedure may be modified or configured to match the desired configuration.

4.1 Configurable Options

The design of the sample boot sequence allows it to be easily configurable. The many options defined in the header files allow the user to choose how the code should execute. These options are summarized in table Table 6.

Table 6. User-Configurable Program Options

Option	Definition Location	Definition	Default Value
USER_ENTRY	ppcinit.h	Specify the name of the entry point in the user C program. Corresponds to main() but isn't named main() due to possible compiler problems.	test_main
ICACHE_ON	ppcinit.h	Specify whether to turn on the Instruction cache. 1 = icache on 0 = icache off	1
DCACHE_ON	ppcinit.h	Specify whether to turn on the data cache 1 = dcache on 0 = dcache off	1
STACK_LOC	ppcinit.h	32 bits specifying the stack address for the user program	0x0007_0000
MMU_ON	ppcinit.h	Specifies whether or not to use the MMU. 1 = MMU on 0 = MMU off	1
PROM_BASE	ppcinit.h	The start address of the address range corresponding to the physical address of the ROM.	0xFFC0_0000
PRAM_BASE	ppcinit.h	The start address of the address range corresponding to the physical address of the RAM.	0x0000_0000
VROM_BASE	ppcinit.h	The start address of the address range corresponding to the virtual address of the ROM.	PROM_BASE

Table 6. User-Configurable Program Options (Continued)

Option	Definition Location	Definition	Default Value
VRAM_BASE	ppcinit.h	The start address of the address range corresponding to the virtual address of the RAM.	PRAM_BASE
IBATxL_VAL	ppcinit.h	Specify the 32 bit value for the lower BAT register for instruction BAT array entry x [x = 0 to x = 3]	See Table 7
IBATxU_VAL	ppcinit.h	Specify the 32 bit value for the upper BAT register for instruction BAT array entry x [x = 0 to x = 3]	See Table 7
DBATxL_VAL	ppcinit.h	Specify the 32 bit value for the lower BAT register for dataBAT array entry x [x = 0 to x = 3]	See Table 7
DBATxU_VAL	ppcinit.h	Specify the 32 bit value for the upper BAT register for data BAT array entry x [x = 0 to x = 3]	See Table 7
text, data, bss locations	ld.script	The locations of the text, data, and bss sections may be specified by the user in ld.script. These addresses control the location of the various sections in the compiled program image, as well as after the relocation of the image. The user can use these address to control whether or not the sections are relocated by specifying an image address that is equivalent to the post-relocation address.	See “GCC Compilation and Linking.”

y

Table 7. Default BAT Register Values

Register	Value	Description
IBAT0L	0xFFC0_0022	BRPN = 1111 1111 1100 000 WIMG = 0100 PP = 10 (read/write)
IBAT0U	0xFFC0_01FF	BEPI = 1111 1111 1100 000 BL = 0000 1111 111 (16 Mbytes) Vs = 1 (valid for supervisor) Vp = 1 (valid for user)
IBAT1L	0x0000_0002	BRPN = 0000 0000 0000 000 WIMG = 0000 PP = 10 (read/write)
IBAT1U	0x0000_03FF	BEPI = 0000 0000 0000 000 BL = 0001 1111 111 (32 Mbytes) Vs = 1 (valid for supervisor) Vp = 1 (valid for user)
IBAT2L	0x0000_0000	BAT_NO_ACCESS
IBAT2U	0x0000_0000	BAT_INVALID
IBAT3L	0x0000_0000	BAT_NO_ACCESS

Table 7. Default BAT Register Values (Continued)

Register	Value	Description
IBAT3U	0x0000_0000	BAT_INVALID
DBAT0L	0xFFC0_0022	BRPN = 1111 1111 1100 000 WIMG = 0100 PP = 10 (read/write)
DBAT0U	0xFFC0_01FF	BEPI = 1111 1111 1100 000 BL = 0000 1111 111 (16 Mbytes) Vs = 1 (valid for supervisor) Vp = 1 (valid for user)
DBAT1L	0x0000_0002	BRPN = 0000 0000 0000 000 WIMG = 0000 PP = 10 (read/write)
DBAT1U	0x0000_03FF	BEPI = 0000 0000 0000 000 BL = 0001 1111 111 (32 Mbytes) Vs = 1 (valid for supervisor) Vp = 1 (valid for user)
DBAT2L	0x0000_0000	BAT_NO_ACCESS
DBAT2U	0x0000_0000	BAT_INVALID
DBAT3L	0x0000_0000	BAT_NO_ACCESS
DBAT3U	0x0000_0000	BAT_INVALID

Each of these options can be configured in order to customize the boot sequence for a particular application. The configurable boot sequence contains #define statements which may be combined to easily create BAT entry values. For example, the default entry for the upper instruction BAT 1 specifies a 32-MByte block size, valid user mode, valid supervisor mode, with a BEPI of 0x00000000. This entry can be formed using the header file defines as follows: IBAT1U_VAL = (VRAM_BASE | BAT_VALID_USER | BAT_VALID_SUPERVISOR | BAT_BL_32M). Refer to the source file for ppcinit.h at the end of this document for details.

4.2 General Initialization

Processor initialization in the sample boot sequence follows the steps outlined in Part II, “PowerPC Processor Initialization.” One of the most important tasks of the boot code is to set the value of the MSR for the user program. Specifically, the MSR is set to enable floating point and machine check exceptions. If the text section relocates from its load location to an address below 0xFFC0_0000, the exception prefix is changed to 0x00000000 by setting the MSR[IP] to 0. In addition, data and instruction address translation may be enabled if the MMU is used. The new MSR value is loaded into machine status save/restore register 1 (SRR1). Upon **rfi**, this value will be copied from SRR1 into the MSR.

The timebase register is initialized to 0x0000_0000 in order to place it in a known state. Also, the machine status save/restore register 0 (SRR0) is modified to contain the address of the user entry point, USER_ENTRY, after the relocation. The address in SRR0 is the address of the instruction to be executed upon an **rfi** instruction.

Additionally, the link register is loaded with an address where execution will resume when the user program completes. In order to provide timing results for benchmarking, the user program will return to the label

save_timebase when complete. The value of the upper and lower time base registers will be stored in memory for later access. Once this operation completes, the code sequence will branch to 0xFFF0_0700 to indicate completion. The user should set a watch or breakpoint at this address to determine when the user program has finished.

The caches are invalidated and disabled during the majority of the init sequence. This prevents program data from being preloaded into the caches, which could unfairly speed up a benchmark. Before branching into the user program, the boot code enables the caches if ICACHE_ON and DCACHE_ON are set to 1 in ppcinit.h. If MMU_ON is defined as 1, it initializes the BAT registers and enables address address translation as well.

4.3 EABI Register initialization

In order for a program compiled with an EABI-compliant compiler to execute properly, registers GPR1, GPR2, and GPR13 must be initialized before branching into the user code as described in Part III, “PowerPC EABI Compliance.” Register 1 will be loaded with STACK_LOC, the location of the stack reserved for the user program defined in ppcinit.h. Care should be taken to ensure that the stack size is sufficient; it does not grow down into the text, data, or bss sections of the program during execution.

In the EABI, GPR2 is used to hold the base of the read-only small data area. It is loaded with the value _SDA2_BASE generated during linking. Similarly, GPR13 holds the small data area base and is loaded with the symbol _SDA_BASE, also generated by the linker.

4.4 Code Relocation

The code relocation depends on variables that are allocated in the file ld.script. The text, data, and bss sections of the program may be relocated from ROM to RAM using these variables.

The first relocation that takes place is the text relocation. The relocation code looks at the ld.script variables _img_text_start and _final_text_start to determine if the text must be relocated. If the two variables are equal, then no text relocation occurs. This typically speeds up execution in a simulated environment, and when the user program to be run is fairly simple. If the user program is large or performs large numbers of iterations, execution may be speeded by moving the text from ROM to RAM if ROM accesses are slow.

The start address of the section to be copied is stored in the symbol _img_text_start defined in ld.script. The length of the copy is determined using the symbol _img_text_end also defined in ld.script. The program starts copying at _img_text_start and copies data to _final_text_start until it reaches the address _img_text_end.

Next, the data and bss sections may be relocated. For standard systems where the boot program exists in a read-only ROM, these sections must be moved so they can be modified by the user program. If the code is not initially located in a ROM, or if the ROM is writeable, then these sections do not need to be relocated. The ROM image location of the data section is stored in the symbol _img_data_start, defined in ld.script. It will be relocated to the address defined in _final_data_start. If _img_data_start and _final_data_start are not equal, the relocation program starts copying from _img_data_start to _final_data_start. When the copy-to address is equal to _final_data_end, defined in ld.script, the copy is complete. If _img_data_start and _final_data_start are equal, the program skips the data copy.

The bss section is not actually copied since it only holds unitialized data. Instead, the region starting at _bss_start and ending at _bss_end,both defined in ld.script, is initialized to all zeroes. This code may be commented out for programs which do not depend on zero-filled bss.

The user may control the ROM image and relocation addresses of the different sections by modifying the file ld.script, as specified in “GCC Compilation and Linking.”

4.5 GCC Compilation and Linking

The compilation and linking procedure for a standalone bootable program is fairly complex. The compiled program should not include most standard libraries, and needs to be in a format that can be copied into a simulated or real ROM device or memory component. Most importantly, the code needs to be located at a specific absolute start point so that it begins execution on system reset. In addition, the executable needs to be built so that references to symbols and variables refer to the location of variables after the relocation to RAM (if any) has occurred. Most of this work is accomplished through the use of a linker script.

Note that this document refers to the target of the build as a "ROM image." Whether this image is actually loaded into a ROM component or some other simulated or real memory device is implementation dependent.

The compilation procedure discussed in this paper uses the GNU cross-compiler which is free and publicly available from many different sources on the internet. The GNU make utility and the GNU assembler and linker are also used.

The transition from .S and .c files to .o files is accomplished using gcc -c :

```
ppcinit.o: ppcinit.h ppcinit.S
     $(CC) -c ppcinit.S

test.o: test.c
     $(CC) -c test.c
```

$(CC) must be defined as the path to the cross-compiler. (See Part V, "Source Files," Section 5.4, "Makefile.") Note that the assembly source file is named ppcinit.S as opposed to ppcinit.s. This causes the preprocessor to run and strip out the C++ style comments. In the makefile, all references to test should be changed to match the name of the user program to be linked with the boot program. The build command for test should be changed to specify the appropriate dependencies and build options.

Once all source files have been compiled, the resultant object files must be linked together into an executable. For this purpose, the GNU linker will be invoked with a custom linker control script. This linker script specifies the starting address for the program, as well as the post-relocation addresses of the text, data, and bss sections. In addition, it defines symbols that are used by the relocation portion of the boot sequence to determine the locations and lengths of the various sections as described in Table 8.

The linker script provides default values for IMAGE_TEXT_START (0xFFF0_0000), TEXT_START(0x0000_0000), IMAGE_DATA_START, and DATA_START. The data section is located at the first appropriately aligned address following the text section. To change these defaults, the user may add definitions for these variables to the makefile, which will pass these options to the linker when it is invoked.

Table 8. ld.Script Variables

Variable	Definition	Value
_img_text_start	The location of the start of the text section in the compiled image—This value is derived from the LOADADDR or the text section.	IMAGE_TEXT_START
_img_text_end	The location of the end of the text section in the ROM image—Derived from the LOADADDR of the text section and the size of the text section.	_img_text_start + SIZEOF(.text)
_final_text_start	The address of the start of the text section after relocation—Derived from the ADDR specified for the text section.	TEXT_START

Table 8. ld.Script Variables (Continued)

Variable	Definition	Value
_img_data_start	The location of the start of the data section in the compiled image— This value is usually equal to the image address of the start of the text section plus the size of the text section.	IMAGE_DATA_START, if defined in Makefile; (LOADADDR(.text) + SIZEOF(.text)) by default
_final_data_start	The location of the start of the data section after relocation— This value is usually equal to the post-relocation address of the start of the text section plus the size of the text section.	DATA_START, if defined in Makefile; (ADDR(.text) + SIZEOF(.text)) by default
_final_data_end	The location of the end of the data section after relocation—This value is equal to the start of the data section plus the size of the data section.	_final_data_start + SIZEOF(.mdata)
_bss_start	The destination start address for the bss section—Typically set equal to the relocation address for the data section plus the length of the data section.	ADDR(.mdata) + SIZEOF(.mdata)
_bss_end	The destination end address for the bss section.	_bss_start + SIZEOF(.bss)

The example .text section is located at 0xFFF0_0000 in the compiled image and at 0x0000_0000 after the relocation. The sample boot code places its first executable instruction at an offset of 0x0100 from the start address using the .space assembler directive. This means that this first instruction will be located at the PowerPC system reset vector, 0xFFF0_0100, and will be executed when system reset occurs.

The text section is composed of the text, read-only data, and global offset table portions from the different .o files. The symbols _img_text_start and _img_text_end are defined for use by the relocation code and refer to the beginning and end addresses of the text section in the compiled image. The address of the text section after the relocation is saved in _final_text_start:

```
TEXT_START = DEFINED(TEXT_START)? TEXT_START: 0x00000000;

IMAGE_TEXT_START = DEFINED(IMAGE_TEXT_START)? IMAGE_TEXT_START:
        0xFFF00000;

.text TEXT_START: AT (IMAGE_TEXT_START)
{
*(.text)
*(.rodata)
*(.rodata1)
*(.got1);
}

_img_text_start = LOADADDR(.text);
_img_text_end = (LOADADDR(.text) + SIZEOF(.text));

_final_text_start = ADDR(.text);
```

Note the use of the `LOADADDR()`, `ADDR()`, and `SIZEOF()` functions. These functions are built in to the linker and are used to obtain information about the sections.

- LOADADDR() returns the absolute load address of the specified section. This address corresponds to the location of the section in the compiled image.
- The ADDR() function returns the location of the named section after relocation.
- SIZEOF() is used to determine the length of a section, in bytes.

In the sample shown above for the .text section, LOADADDR(.text) returns 0xFFF0_0000 and ADDR(.text) returns 0x0000_0000 for the default case.

The data section of the linker script is a bit more complex since the location of the data section is dependent upon the location and length of the text section. It contains all initialized, modifiable data, including the small data sections. If the data is relocated during the initialization sequence, we must specify its new location so that references to variables refer to the relocated copy.

In this example, the data section will be located immediately following the text section data both in the compiled image and after relocation. In order to avoid confusion, the all-inclusive data section is renamed. This example calls it .mdata:

```
DATA_START = DEFINED(DATA_START)? DATA_START: (((ADDR(.text) +
    SIZEOF(.text)) & 0xFFFFFFE0) + 0x00000020);

IMAGE_DATA_START = DEFINED(IMAGE_DATA_START)? IMAGE_DATA_START:
    (((LOADADDR(.text) + SIZEOF(.text)) & 0xFFFFFFE0) + 0x00000020);

.mdata DATA_START: AT (IMAGE_DATA_START)
{
_final_data_start = .;
*(.data)
*(.data1)
*(.sdata)
*(.sdata2)
*(.got.plt)
*(.got)
*(.dynamic);
_final_data_end = .;
}

/* Now save off the start of the data in the image */
_img_data_start = LOADADDR(.mdata);
```

The _final_data_start and _final_data_end symbols indicate the post-relocation start and end addresses of the data section. In addition, the symbol _img_data_start holds the start address of the data section in the ROM image. This information will be used during the relocation of the data.

The linker script treats the bss section much like the data section. The only difference is that it is not necessary to know the location of the bss section in the ROM image. The relocation program only needs to know how big the bss is so it can zero out an appropriate section of memory in RAM for uninitialized data. For the sample boot program, the bss section will be located directly after the data section, and the symbols _bss_start and _bss_end are used to determine the length of the bss section:

```
.bss (ADDR(.mdata) + SIZEOF(.mdata)) :
{
_bss_start = .;
*(.sbss)
*(.scommon)
*(.dynbss)
*(.bss)
*(COMMON);
_bss_end = .;
}
```

In some cases, it is possible that the address range located at 0xFFF0_0000 is writeable. In this instance, the user may not wish to relocate the sections from the load address. The easiest way to do this is to specify equivalent relocation and load addresses for the text section. The sample boot program checks for this before performing a copy. Since all other section addresses are based on the location of the text, this is the only

change needed in order to leave the entire image in ROM space. This change is accomplished by defining identical IMAGE_TEXT_START and TEXT_START variables in the makefile.

Finally, some users may wish to relocate only those sections (data and bss) which are modified during program execution. The easiest way to do this is to specify an absolute relocation address for the data section, and allow the bss to be located immediately following the data. The locations of the sections in the compiled image remains the same. To accomplish this, define IMAGE_TEXT_START and TEXT_START to be identical in the makefile. Then define a DATA_START that specifies the desired location of the data section during execution. Using this method, the data section will still follow the text section in the load image but will be moved to DATA_START before the user program begins execution. The text section will remain at its load location, reducing the time required for the copy.

The linking phase of the build for the ppcinit program produces a .elf file organized as specified in ld.script. In addition, the -fnobuiltin option has been specified to prevent linking with standard libraries. This .elf file can be loaded and executed. For environments that do not have elf loading capability, the executable may be translated into Motorola S-Record format using the GNU objcopy utility, specifying the output file format as S-record:

```
go.srec: go.elf
    $(PREFIX)/bin/$(TARGET)—objcopy -O srec go.elf go.srec
```

This S-record may be loaded into ROM and executed.

4.6 Using the Sample Boot Sequence

Using the sample boot sequence requires setting up the configurable parameters to describe a particular hardware configuration. The following list describes this process:

In ppcinit.h:

1. #define either MPC603e or MPC750 to match the processor type. One of these must be defined for the code to work properly.
2. To use the instruction cache, #define ICACHE_ON to 1. To disable the instruction cache, define it to 0.
3. To use the data cache, #define DCACHE_ON to 1. To disable the data cache, define it to 0.
4. #define STACK_LOC to the desired location of the stack for the user program.
5. To use the MMU, #define MMU_ON to 1.
6. If MMU_ON is defined, the BAT setup macros must be defined in order to provide basic address translation and protection. Fill in the [ID]BATx[UL]_VAL macros with the values for the associated BAT array entry. Typically, #define a base physical address (like (PROM_BASE and PRAM_BASE in the sample file) and a base virtual address (like VROM_BASE and VRAM_BASE in the sample file) for each memory region. Use these addresses, along with the provided BAT macros, to form an entry. As an example, to define a data region representing a ROM starting at the physical address 0xFFF0_0000 that is cache inhibited and has read/write access, #define PROM_BASE to 0xFFF0_0000. Then #define DBAT0L_VAL to be PROM_BASE | BAT_CACHE_INHIBITED | BAT_READ_WRITE. Refer to the ppcinit.h source file for a list of available macros.
7. Repeat step 6 until instruction and data BAT entries have been created for all memory regions to be used by the user program.
8. Fill in entries for the remaining unused BATs with BAT_NO_ACCESS for the lower BAT register, and BAT_INVALID for the upper BAT register.
9. #define USER_ENTRY to the name of the entry function for the user program. Avoid using main() as this causes some compilers to try to link in standard crt0 or eabi start code.

In makefile:

1. To locate the loadable text section at an address other than 0xFFF0_0000, define IMAGE_TEXT_START to the desired value.
2. To define the execution address of the text section, change the definition for TEXT_START to match the desired address. This defaults to 0x0000_0000.
3. By default, the data section will be located immediately following the text section in both the load image and during execution. To change this, define DATA_START and IMAGE_DATA_START to the appropriate values.
4. List the C source files for the user program in the definition for C_SRC.

The code may now be built and executed for the target platform.

4.7 Limitations of the Sample Boot Sequence

The sample boot sequence is intended to be used in a controlled environment and is designed to be as minimal as possible. As a result, there are some limitations to its design and use.

1. The image should be built to be initially located at either 0xFFF0_0000 or 0x0000_0000.
2. Memory is mapped via the BAT registers. The segment registers and page tables are not used.
3. The segment registers, page table pointer, and page tables are not initialized. Care should be taken to ensure that programs do not generate references to addresses in ranges not mapped by a BAT register. Doing so causes the processor to attempt to search the page table (whose location has not been defined and could point anywhere) for a translation. This could possibly result in reading/writing to random locations in memory.
4. No exception handling code is provided. With the exception of system reset, the exception vector locations contain the illegal opcode for PowerPC (0x0000_0000).
5. The code only initializes the processor; it does not initialize any peripheral devices and is not designed to be run in a system with a memory controller such as an MPC106 or MPC105. Additional code must be added to handle these situations.
6. Programs should avoid making stdio calls such as printf since there is no mechanism for handling this.
7. The sample sequence only performs setup necessary for standard C compiles. C++ programs and programs written in other languages may require additional support.

Part V Source Files

The following sections contain the complete source code for the files ppcinit.S, ppcinit.h, ld.script, and makefile.

5.1 ppcinit.S

```
/*
// This file contains generic boot init code designed to be run on
// PowerPC processor simulations that just need minimal setup.
//
// This code has also successfully been used to run processor-intensive
// benchmarks (written in C) on minimal hardware boards such as
// Excimer.
//
```

```
// This code is designed to be run from Power-up or hard reset;  running from
// soft reset may require additional operations such as cache invalidation,
// that are not supplied here.
//
// Once the hw init is complete, this code branches into the
// USER_ENTRY defined in the user code
//
// This code has been tested on the MPC603e and MPC750.
// Architectural differences between processors with respect to cache
// types and sizes, cache management instructions, number of TLB
// entries, etc, may require changes to be made to this code before it may
// be used successfully on other processors.
*/

.file   "ppcinit.S"

// NOTE: If you need to define variables, put them at the end!  The _start
// symbol needs to be at hreset in order for this code to run automatically
// on hard reset.

#include “ppcinit.h”

.text
.global _start

          .space  (0x0100)                                  // locate at hreset vector

// this should now be located at the reset vector
_start:
          b       system_reset

        .space  (0x3000)        //space past exception space
// here's the real startup code, located outside the exception vector space

system_reset:
        addis.  r0,r0,0x0000    //let’s make sure that r0 is really 0x0

        // from reset, the BATs are in an unknown state on most PPCs.
        // Invalidate them all to avoid error states

If we're using the MMU, we need to set up the BAT registers.
Since we don't have a nice operating system handling page
table entries and the like for us, the BATs provide the
easiest translation mechanism.

The User must define the BAT mappings here.  For unused BATs, specify the
BAT as INVALID and having NO_ACCESS as shown for bats 2 and 3 below.

This code maps everything, including the ROM and instruction space as
read-write because we're in a simulator and might want to do something
that you wouldn't be able to do on real HW.  In a real system, ROM and
instruction space is typically mapped Read-only.
